Method to Determine the Dosage of Bituminous Tack Coat in Function of the Texture of Milled Asphalt Layers to be Overlaid

Abstract

In the rehabilitation of flexible pavements with asphalt layers, it is necessary to apply a bituminous tack coat with a pre-established dosage, which usually does not take into account the degree of texture generated if a milling operation is previously performed, since this increases the surface at the interface. On the other hand, when milling, grooves are obtained that could lead to the runoff of bitumen emulsion with excessive deposition in their valleys due to dosages greater than those needed. This work analyzes the above mentioned and achieves a compromise solution, with its corresponding method of application, based on the mechanical behavior obtained with different degrees of texture and validated for typical materials used in Argentina.

Key words: Road Engineering, Asphalt Overlays, Pavement Milling, Bituminous Tack Coat

1. Introduction

During the operation of a flexible pavement road, activities are carried out aimed at its rehabilitation, sometimes eliminating part of the wearing course by means of milling techniques, avoiding the influence of the rutting of the existing layer and eliminating the thickness increase (Martínez-Echevarría 2012, NCHRP 2004, Miller and Bellinger 2003). This task requires the use of rotating equipment, equipped with milling tools that may have different characteristics, allowing several degrees of texture, different from the original surface, which can be considered "smooth" in relative terms (Delbono 2014, Wirtgen 2015).

Before placing the overlay, it is necessary to provide an asphalt emulsion tack coat to generate an adequate interface (Bussard 2014), so that if the existing pavement has a good structural condition, the stresses and deformations generated by the traffic effect do not affect the expected lifetime (Espinoza 2015, Montetrusque et al. 2015). Considering that milling produces

1
2
3 a grooved surface which increases the existing pavement surface, a corresponding increase in
4
5 tack coat will be necessary when compared to a non-milled surface. There are few studies that
6
7 have addressed this subject. For this reason, this work was developed, within the framework of
8
9 a doctoral thesis in materials engineering, carried out mainly in LEMaC, the Road Research
10
11 Center of the Universidad Tecnológica Nacional, Facultad Regional La Plata, Argentina.

12
13
14 The objective of this study is to evaluate the effect of the increase of surface area of the milled
15
16 pavement on the tack coat dosage.
17
18
19

20 21 22 **2. State of the art**

23
24 The structural analysis of the interface will be conditioned to the structural model that will be
25
26 used (EICAM 1998, Uzan et al. 1978). Specifically, in multilayer flexible pavements, traffic
27
28 loads induce stresses in the structure that are absorbed by the set of different layers, from the
29
30 upper layer to the lower layers of the pavement and the subgrade (Giovanon and Buono 2008,
31
32 Yaacob et al. 2014); thus, an adequate modeling of the interface leads to optimizing the costs
33
34 of a rehabilitation (Romanoschi 1999) if the incidence of milling and its characteristics in each
35
36 particular case is considered (Brown and Brunton 1984). Most researchers developed new
37
38 prototypes to improve their investigations, demonstrating that shear stress tests are a good and
39
40 effective method of analysis (Giovanon and Pagola 2012, Santagata et al. 2009, Diakhaté et al.
41
42 2011, Raposeiras et al. 2013). The mechanical models of interfaces express the relationship
43
44 between the shear displacement along the interface plane and the normal and shear stresses.
45
46 Evaluating the static stresses to failure, Romanoschi (1999) reported that the results obtained
47
48 could be represented with a simplified model, which consists of two stages, the elastic response
49
50 and the friction one (for each representative reference temperature), as shown in Figure 1. In
51
52 the first stage the Shear Displacement (TD) is proportional to the shear stress (Goodman's
53
54 model), the proportionality being the interface reaction modulus (K) in the horizontal direction,
55
56
57
58
59
60

1
2
3 up to the Maximum Shear Strength (S_{max}) when failure takes place. Once the interface fails,
4
5 the second stage starts and can be described as friction between layers (characterized by the
6
7 friction coefficient μ).
8
9

10 **[Figure 1 near here]**

11
12 The relationship between the existing surface and the applied overlay depends mainly on the
13
14 amount of residual asphalt binder in the bituminous emulsion tack coat (parameter used to
15
16 specify the tack coat dosage) (Ricci 2011). The National Highway Administration of Argentina
17
18 (in Spanish *Dirección Nacional de Vialidad*, DNV) specifies the use of a cationic rapid setting
19
20 emulsion with a dosage that ensures a minimum shear resistance of 0,7 MPa at the interface
21
22 according to EN 12697-48 Standard with SBT method (DNV 2017). But there is no particular
23
24 specification for pavement rehabilitation when the existing layer is subjected to a surface
25
26 milling as can found in USA for example (Gierhart 2018). Figure 2 shows an image of the SBT
27
28 device.

34
35
36
37

38 **3. Materials and Methods**

39
40 The methodology consisted of the following steps:

41 42 *3.1. Determination of the optimum tack coat content for non-milled surface*

43
44 In order to evaluate the influence of the surface increase at the interface of the bilayer systems,
45
46 it is necessary to define first a tack coat dosage for the case of the non-existence of milling in
47
48 the interface ("smooth" surface). For this purpose, the bilayer system was studied in laboratory
49
50 with a double specimen prepared with two layers of asphalt mixture and a rapid setting cationic
51
52 asphalt emulsion for the tack coat application at the interface. A dense hot asphalt concrete
53
54 with maximum aggregate size of 19 mm (CAC-D19) for both the upper and lower layers of the
55
56 double specimens was selected. Considering the approximate allocations recommended by the
57
58
59
60

1
2
3 reference literature, it was decided to analyse the tack contents of 0,0 l/m², 0,1 l/m², 0,2 l/m²,
4 0,3 l/m² and 0,4 l/m². By establishing 3 replicates per each content, 15 double specimens were
5
6 manufactured, as can be seen in Figure 3. Density of the specimens was determined and the
7
8 results presented a tendency to the normal distribution with an average value of 99.4 % with
9
10 respect to the Marshall reference density, which is considered a sufficiently approximate value,
11
12 since it verifies the specified methodology.
13
14
15

16
17 **[Figure 3 near here]**
18

19
20 There are numerous tests worldwide, since different researchers have not yet agreed on which
21
22 to use (Tosticarelli 2002, Muench and Moomaw 2008). However, pure direct shear tests
23
24 represent the most common ones in the applying shear displacement and recording shear stress
25
26 (Giovanon 2012). The test selected in the present work subjects the specimens to pure shear
27
28 stress in a parallel direction to the interface of the tack coat, Figure 4.
29

30
31 **[Figure 4 near here]**
32

33
34 Based on the data collected and the experiences by Delbono (2014) and Ricci (2011) at the
35
36 LEMaC facilities, it was decided to generate the shear stress in the plane to be evaluated at a
37
38 controlled piston speed of 1,27 mm/min and establish the test temperature at 20 °C.
39

40
41 The research team led by D'Andrea (2013) revealed that double cylindrical specimens prepared
42
43 with the Marshall compactor can be made by applying the compaction only on one surface.
44
45 Ricci (2011) carried out studies of series of double specimens made with an analogous
46
47 methodology of compaction, determining that the difference of densities along the height of the
48
49 specimen are statistically negligible. To carry out this test, the bituminous tack coat is applied
50
51 between both layers with a standardized curing process in the laboratory, using a forced
52
53 ventilation oven at temperatures close to 60 °C (Yaacob et al. 2014). These double specimens
54
55 are molded with a thickness of 50 mm for both the base layer and the overlay. The clamps that
56
57 surround the upper and lower part of the double specimen were separated by about 30 mm to
58
59
60

1
2
3 allow the development of the milled interface, generating in addition to the own deformation
4 that takes place at the interface another deformation close to the interface related to the
5 specimen in this area, as can be seen in Figure 5. Therefore, the tangential deformations and the
6 shear stresses are different from those obtained with the SBT, where the clamps are separated
7 by a minimum distance. For this reason, the results of TD and S_{max} to be obtained in this work
8 are only comparatively relative to each other and not to those generated by other test
9 methodologies.

13
14
15
16
17
18
19 **[Figure 5 near here]**

20
21
22 Figure 6 shows a set of resulting type curves and the analysis parameters obtained for the series
23 of samples tested, corresponding to the $0,1 \text{ l/m}^2$ dosage. In this figure, the curves for each
24 sample have been displaced on the displacement axis a distance corresponding to $4,0 \text{ mm}$, to
25 allow a better observation.

26
27
28
29
30
31 **[Figure 6 near here]**

32
33
34 *3.2. Verification of the minimum shear resistance according to Argentine Specifications*
35 *with SBT (UNE- EN 12697-48 Standard)*

36
37
38 Since the Argentine technical specification establishes a minimum S_{max} of $0,7 \text{ MPa}$ according
39 to SBT (DNV 2017), which is different from the test applied in this study, the question arises
40 whether the results obtained in the implemented test are comparable to the specified one.

41
42
43 Considering that LEMaC laboratory does not have the SBT device but does have the LCB test,
44 and that there is a correlation between them, the latter was used to do the aforementioned
45 verification. The LCB test is one of the two tests admitted by the Spanish specifications, which
46 according to NLT-382 standard, allows the use of both devices, named A (SBT with Leutner
47 device) and B (LCB Test). These two procedures were collected in NCHRP Report 712 by
48 Mohammad et al (2012) and are well-known by experts in the field. For the correlation, it was
49 considered what was observed by Berenguer et al. (2017) with respect to the Spanish
50
51
52
53
54
55
56
57
58
59
60

1
2
3 specification: device B showed 20% lower shear stresses than Device A.
4

5 Therefore, complementary tests were carried out by means of LCB Testing equipment, on
6 double specimens of 100 mm in diameter, at a speed of 2,5 mm/min and at temperature of 20
7 °C as required by the standard, with the results being increased by 20% to compare them to the
8 ones obtained from the SBT Test. Double specimens were moulded by means of the procedure
9 described in the previous section, with the optimum tack coat content obtained also in the
10 previous stage.
11
12
13
14
15
16
17
18

19 3.3. *Determination of the optimum tack coat content for milled surfaces*

20 Milling equipment produces various surface texture results, Figure 7, such as standard milling
21 (left), fine milling (centre) and micro-milling (right) (Bonfim 2008).
22
23
24
25

26 **[Figure 7 near here]**
27

28 Taking into account some values obtained from the literature review, six milling patterns with
29 the characteristics shown in Table 1 were considered for this study (The Asphalt Contractor
30 2011, Wirtgen 2013, Montetrusque et al. 2015, Bussard 2014).
31
32
33
34
35

36 **[Table 1 near here]**
37

38 This step analyses whether it is necessary to increase the dosage proportionally to the increase
39 of area generated by the resulting texture after milling. The doubt arises because it is likely that
40 an excessive increase in the amount of tack coat is not distributed evenly over the milled
41 surface, due to the emulsion flow, which can lead to an excessive deposit in the valley of the
42 grooves. To analyse this, a laboratory experience is carried out on a specimen that simulates
43 milling of Case 3. The dosage of tack coat proportionally increased to the increment of the
44 contact area at the interface is applied in the laboratory with a brush. This specimen is then
45 sawn and observed with an Olympus SZ61 magnifying glass, with an approximate
46 magnification of 45x, achieving images like those in Figure 8. It is confirmed the validity of
47 the hypothesis made, since it is clear that the deposition of bituminous tack coat in the valleys
48
49

53
54
55
56
57
58
59
60

1
2
3 of the milling is bigger than that obtained in the ridges.
4

5 **[Figure 8 near here]**
6

7
8 Next, situations that represent an increase of the optimum dosage in 3/3, 2/3, 1/3 and 0/3 of
9
10 proportion of the contact area increase at the interface are studied to take into account the
11
12 milling process. Therefore, the optimum dosage was multiplied by a coefficient of increase (*CI*)
13
14 which was calculated from the ratio between the milled area and the smooth area and then
15
16 varied as 100%, 66%, 33% and 0%.
17

18
19 These 4 situations were considered for the 6 cases of milling simulation described in Table 1.
20
21 Double specimens to be analysed were manufactured, establishing a number of 3 replicates per
22
23 case. After casting the base layers, the surface sawing of the specimens is proceeded, as shown
24
25 in Figure 9 (for a specimen corresponding to Case 5). Figure 10 shows the specimens prepared
26
27 for Situation 4, as an example. Again, Marshall density is determined and given that the results
28
29 verify the moulding procedure adopted the test can be performed. It should be noted that,
30
31 because the main bending of the pavement is in its longitudinal direction and that the milling
32
33 presents its toothed surface in this direction, the tests are performed with the double specimen
34
35 arranged according to the orientation that can be observed in Figure 11.
36
37

41

42 **[Figure 10 near here]**
43

44 **[Figure 11 near here]**
45

46 3.4. *Correlation between dosage increase in milled surfaces and texture*

47
48

49
50 By having the results of the increments of area $\Delta(\text{Area})$ registered with different combinations
51
52 of width and depth of the grooves, regression models can be found (by numerical simulation
53
54 for example) that allow estimating $\Delta(\text{Area})$ in future applications, from the diameters obtained
55
56 using an analogous test methodology to that of the Sand Patch Test (IRAM 1997 Argentine
57
58 Standard). Following this work line, the authors defined a formula that allows estimating the
59
60

1
2
3 Coefficient of the Area Increase (*CAI*), that is, the ratio between the surface area of the milled
4 interface with respect to the surface area of a smooth interface, as a function of the Diameter of
5 the Sand Patch (*DSP*) resulting for a sand volume of 40 cm³: $CAI = 5,03 DSP^{-0,41}$. (Rivera et
6
7
8
9
10 al. 2017).

11
12 The correlation was validated in laboratory on samples representing the 6 established cases,

Then the *DSP* were measured in orthogonal directions and the averages were taken as reference
for the cases studied (Table 2).

[Figure 12 near here]

[Table 2 near here]

Figure 13 shows a cross section that comes from a sample extracted on site after the milling
process (in the upper image) and an image of the section achieved for Case 3 (in the lower
picture), which can be assumed characteristic of the actual situation (both images on the same
scale). The comparative visual analysis demonstrates the similarity achieved with the milling
simulation technique.

[Figure 13 near here]

In addition, Table 3 shows the average and standard deviation values obtained from field
observations, which are representative for the 6 cases to be analysed, according to the
dimensions shown in Figure 14.

[Table 3 near here]

[Figure 14 near here]

3.5. *Application of the methodology to a real case*

Studies were carried out on a road work where an asphalt layer was milled and there is a
remaining thickness of asphalt mixture to be overlaid. The work examined is the Provincial
Road No. 215, in a section that will be subjected to carriageway widening and pavement

1
2
3 rehabilitation between the towns of Coronel Brandsen and San Miguel del Monte, Province of
4 Buenos Aires, Argentina. Among the items of this work are the milling of the asphalt layer in
5 5 cm depth, the application of a tack coat and the placement of an overlay type CAC-D19. On
6 site, a remaining asphalt layer of approximately 8 cm thick is observed, over a Portland cement
7 concrete pavement. So, texture determinations were made in order to measure DSP values with
8 the methodology analogous to the developed Sand Patch Test, Figure 15.
9

10
11
12
13
14
15
16
17 **[Figure 15 near here]**

18
19 **[Figure 16 near here]**

20
21 Next, 9 cores were extracted with a diameter of 10 cm, from the remaining asphalt mixture in
22 a single line, in the sector where the aforementioned determinations were made; Figure 16. The
23 cores were cut into 5 cm height, and the remaining material was kept and used for asphalt
24 bitumen content extraction and aggregates recovery. Since the results obtained were similar to
25 those of the asphalt mixture used in the laboratory; the tack coat was applied in the same dosage
26 for the comparative analysis (named Dosage I). Considering the parameters defined in the
27 previous section, three dosages were applied in total, corresponding to the following situations:
28

- 29 • Dosage I: tack coat dosage established for the interface on smooth surfaces.
- 30 • Dosage II: tack coat dosage using the formula developed to estimate the *TCIC*.
- 31 • Dosage III: tack coat dosage calculated from direct increase of the contact surface area at
32 the interface, using the *CAI* parameter.

47 An asphalt mixture was prepared in laboratory and used to simulate the overlay in fabrication
48 of the double specimens, which were tested with the developed equipment.
49

50 51 52 53 **4. Results and Discussion**

54 55 *4.1. Optimum tack coat content for non-milled surface and specification verification*

56
57
58 A summary in Table 4 collects the results of maximum shear stress S_{max} and displacement TD
59
60

1
2
3 at breaking point for the tack coats dosages studied.
4

5 **[Table 4 near here]**
6

7 A highest S_{max} value attainable in a dosage between 0,25 l/m² to 0,3 l/m² can be deduced. The
8 observed fact is verified by elaborating the samples with 0,25 l/m² of bituminous tack coat. An
9 average $S_{max} = 0,325$ MPa is obtained, which is very close to that obtained for 0,3 l/m² dosage.
10
11 An optimum dosage of 0,25 l/m² is selected because this means a similar response with less
12
13
14
15
16
17 tack coat.
18

19 Three specimens (A, B and C) manufactured with this dosage, 0,25 l/m², were tested with LCB
20
21 shear device and the results obtained are shown in Table 5. Figure 17 shows an image of the
22
23 device during the performance of the tests. In all cases, the breaking occurred at the interface.
24
25 According to the results obtained from S_{max} (0,898 MPa in average), it can be deduced that
26
27 these bilayer specimens meet the values specified by the Highway Administration, ratifying
28
29 the analysed dosage of 0,25 l/m².
30
31
32

33 **[Table 5 near here]**
34

35 **[Figure 17 near here]**
36

37 *4.2. Analysis of shear strength for the cases studied with milled surfaces and correlation*
38
39 *between dosage increase in milled surfaces and texture*
40

41 Six different milling patterns (Table 1) of texture were prepared on the bottom specimens,
42
43 which were adhered to the top layer with 4 different dosages:
44
45

- 46 – Situation 1: optimum tack coat content increased proportionally to the surface area increase
47
48 (being the coefficient of increase, CI, the ratio between the milled area and the smooth
49
50 area)
51
- 52 – Situation 2: optimum tack coat content increased by 66% of the area increase
53
- 54 – Situation 3: optimum tack coat content increased by 33% of the area increase
55
- 56 – Situation 4: optimum tack coat content obtained for the smooth surface
57
58
59
60

1
2
3 All double specimens were tested with the developed equipment used for the smooth surface
4 optimum tack coat content determination. In Situations 1 and 4, the specimen breaking occurred
5 mostly in the area covered by the tack coat, while in Situations 2 and 3 the specimen breaking
6 took place partly in the tack coat and partly in the texture of the specimen in the interface. The
7 results obtained allow the development of Table 6 and Table 7, where the average values of
8 S_{max} and TD , respectively, are reported for the corresponding values of coefficient of increase
9 of the tack coat (CI s), in each case and each situation.

10
11
12
13
14
15
16
17
18
19 Situation 3 shows the highest results of shear stress. So the corresponding values of CI were
20 defined as the Tack Coat Increment Coefficients ($TCIC$) and were used in the model resulting
21 from the whole experience to establish the Increased Tack Coat Dosage ($ITCD$) from the Tack
22 Coat Dosage determined for the smooth interface (TCD), by means of the formula $ITCD =$
23 $TCIC \cdot TCD$.

24
25
26
27
28
29
30
31 **[Table 6 near here]**

32
33 **[Table 7 near here]**

34
35 To determine the $ITCD$ s as a function of the DSP s, it is then necessary to correlate the values
36 obtained for each case, collected in Table 2, with the established optimum CI s (assumed now
37 as the $ITCD$ s). Table 8 shows the values of both variables to be correlated and Figure 18
38 presents the graph with the correlation obtained.

39
40
41
42
43
44
45 **[Table 8 near here]**

46
47 **[Figure 18 near here]**

48
49 As shown in Figure 18, a potential function can be fitted by regression to the point cloud, which
50 allows obtaining a coefficient of determination $R^2 = 0,99$, which complies with the empirical
51 threshold generally established for studies of this type ($R^2 = 0,90$) (Bello 2016). The formula
52 that finally allows to establish the $TCIC$ according to the DSP , resulting for a sand volume of
53 40 cm^3 , is then $TCIC = 2,014 \times DSP^{-0,184}$.

4.3. Analysis about the methodology proposed

In a road work, several homogeneous sections to be milled and rehabilitated may be identified, either because this task is carried out with different equipment or with the same equipment but with some adapted parts (for example, for maintenance reasons: change of milling grinds, modification of the milling drum, etc.) or by the same variability in the use of such equipment and its operator, etc. The methodology proposed here can be used starting from some direct measurement for determining the optimum dosage to be used in the case of a smooth interface. Then it is necessary to adjust the dosage according to the measurements made using the methodology analogous to the Sand Patch and the application of the developed model, for each type of homogeneous section identified in the work. Another way of using the procedure is extracting cores from the wearing course after the milling process and having previously made the corresponding measurements with the methodology analogous to the Sand Patch developed, as a "test section" in each homogeneous section. With these cores and with the material to be used in the overlay, double specimens are prepared and the optimum content of tack coat is determined for the interface with that specific milling texture. This allows applying the model developed in inverse mode on that established dosage, in such a way as to determine virtually what the optimum dosage of tack coat would be if the test was carried out for the case of smooth interface. Once this dosage is calculated, the adjustment is then made according to the measurements taken using the methodology analogous to the Sand Patch and the application of the model developed in each type of homogeneous section registered in the work, as in the first option.

4.4. Application of the methodology developed to a real case

Table 9 shows the measured *DSP* values on the milled surface of the pavement, which lead to an average final average *DSP* value of 21,6 cm.

[Table 9 near here]

1
2
3 Next, with the 9 cores extracted from the pavement double specimens were prepared using three
4
5 different dosages:

- 6
7
8 – Dosage I: tack coat dosage established for the interface on smooth surfaces.
9
10 – Dosage II: tack coat dosage using the formula developed to estimate the *TCIC*.
11
12 – Dosage III: tack coat dosage calculated from direct increase of the contact surface area at
13
14 the interface, using the *CAI* parameter.
15
16

17 The prepared double specimens are shown in Figure 19 (Dosage I on the left, Dosage II in the
18
19 centre and Dosage III on the right). The specimens tested in the manner indicated above produce
20
21 the average results summarized in Table 10.
22

23
24 **[Figure 19 near here]**

25
26 **[Table 10 near here]**

27
28 Although the tests carried out do not allow establishing if the optimum dosage is achieved, it is
29
30 observed that the highest average results of *Smax* and *TD* are obtained with Dosage II.
31
32 Therefore, these results are related to those obtained in the laboratory experiments, noting that
33
34 the results obtained using a core extracted from an existing pavement, which was milled in the
35
36 work and a new asphalt “overlay” manufactured in laboratory, present results lower than those
37
38 obtained with laboratory base layers (with simulated milling) and new overlay mixtures also
39
40 prepared in laboratory. This finding is consistent with what was expressed by Berenguer et al.
41
42 (2017).
43
44
45
46
47
48

49 **5. Conclusions**

50
51 Based on the studies carried out, it can be concluded that:

- 52
53
54 • The establishment of the dosage of an asphalt tack coat at the interface between asphalt
55
56 layers of a pavement in rehabilitation, where the previously existing layer is subjected to
57
58
59
60

1
2
3 a surface milling, is a subject that had not been studied deeply, at least as far as regarding
4
5 the existing materials in Argentina.
6

- 7
8 • To address this issue, it is useful to start from the knowledge of the texture degree
9
10 generated by the milling process, given the existing spectrum obtained, for which a test
11
12 methodology developed analogous to that of the Sand Patch Test can be adopted.
13
- 14
15 • Through the results of this application it is possible to establish, thanks to the model
16
17 proposed here, the Tack Coat Increase Coefficient to be used to affect the optimum tack
18
19 coat content obtained for the case of smooth interface (without milling).
20
- 21
22 • There are various procedures contemplated in this work, that allow the application of the
23
24 analysis methodology resulting from the studies carried out in homogeneous sections of
25
26 milling of road works.
27
- 28
29 • One of these procedures has been used in a work experience, achieving results that are
30
31 consistent with those previously obtained in the laboratory, which is a contribution to its
32
33 validation.
34
35
